Seventh Annual Illinois Corn Performance Tests 1940

By R. R. COPPER, G. H. DUNGAN, A. L. LANG, J. H. BIGGER,
BENJAMIN KOEHLER, and OREN BOLIN¹

OF THE 7,551,000 acres of corn in Illinois in 1940, 77 percent or 5,814,270 acres was planted to hybrids. This is the largest acreage of hybrid corn on record in the state. The extensive use of hybrids was responsible for a relatively high state average yield, 44 bushels an acre, in spite of a shortage of moisture in many important corn-growing areas. The average yield for the previous ten years was 36 bushels an acre.

SCOPE OF THE TESTS

Three hundred eighty-six hybrids and 26 open-pollinated varieties were included on twelve Illinois corn-performance test fields in 1940, the largest number of hybrids ever entered in the Illinois test. Sixty-seven companies and individuals entered hybrid seed, and twenty-five companies and individuals furnished seed for the open-pollinated varieties.

Two new testing fields were included, one at Mt. Pulaski in Logan county and the other at Greenfield in Greene county. Five fields in the north-central and central sections of the state had 75 entries each. The other fields had 60 entries each, except Albion, which had only 53. Six open-pollinated varieties were used on the Albion field as a check; 5 were used on each of the other fields. Because of the number of producers desiring to submit seed, it was necessary to limit the number of kinds each could enter.

Seed samples were obtained directly from the warehouses of the producers entering the corn, except in a few instances where small quantities were shipped to the Experiment Station by the producers. These small samples and all samples taken from less than five different bushel lots are marked with an asterisk (*) in the tables.

Records were made of total yield, sound yield, percent of moisture in grain at harvest, lodging resistance, and soil adaptability. On the Round Lake field and the Kings field a moisture test was made a little over a week after the first killing frost.

¹R. R. COPPER, Assistant in Crop Production, G. H. DUNGAN, Chief in Crop Production, A. L. LANG, Assistant Chief in Soil Experiment Fields, BENJAMIN KOEHLER, Chief in Crop Pathology, and OREN BOLIN, Associate in Plant Genetics, Illinois Agricultural Experiment Station; J. H. BIGGER, Associate Entomologist, Illinois State Natural History Survey.

SOIL CHARACTERISTICS OF FIELDS

The fields chosen for the 1940 tests were, on the whole, medium to high in productivity. In locating a field, effort was made to select a soil type that occurs extensively in the region represented by the field. Furthermore care was taken to have each field as nearly uniform as possible, both in soil type and in drainage conditions. However, at Reddick the surface soil was alkaline in reaction, and the texture varied from sandy silt loam to clay loam. At Paxton the depth to

unleached compact glacial till was variable. The south half of the testing field at Shobonier was a "slick spot."

The approximate location of the twelve test fields is shown by the map on page 177. General information on soil characteristics and soil-management practices is indicated in Table 2.¹

METHOD OF PLANTING

In order that the trials might be carried on under actual farm conditions, the test plots were located within a larger cornfield. The test plot was planted by hand on the day the rest of the field was planted. The rows of the test plot were joined with those of the surrounding corn so they could be cultivated with the rest of the field.

On all but the Modoc field each entry (variety or hybrid) was planted in 10 plots, each plot being 12 hills long and 2 rows wide. At

¹HERMAN WASCHER, Assistant Chief in the Soil Survey, determined the soil type, uniformity, and physical characteristics of each field. H. J. SNIDER, Assistant Chief in Soil Experiment Fields, made the chemical analyses.

Modoc 30 of the 60 entries were planted in 8 plots and 30 were planted in 7 plots.

All plots were planted 3 kernels to a hill, and the only correction made for imperfect stand was to adjust the yields for missing hills. All seed was treated with organic mercury dust before planting.

Entries were arranged in controlled random order. With the

Location of 1940 test fields

Twelve fields, distributed so as to represent the more important climatic areas of the state, were used in the 1940 general-performance tests; two others, Sibley and Urbana, were used for soil-adaptability tests. All these fields were, on the whole, medium to high in productivity.

Soil samples collected June 3, 4, 6, and 7, 1940.

few exceptions indicated in the tables of results, all plots of each entry were harvested.

SEASONAL CONDITIONS

Growing conditions in 1940 were more favorable at Round Lake in northeastern Illinois and at Kings in northern Illinois than on any of the other corn-performance fields.

Temperatures during May were a little below average, but during the rest of the year temperatures were favorable for corn. An abundance of rain in the northern part resulted in good corn yields and caused the grain to carry a relatively high amount of moisture at harvest. Grain samples were taken on the Kings and Round Lake fields on October 8 and 9 respectively in order to determine the condition of the corn about a week after the first killing frost.

The Cambridge field in west north-central Illinois received about the right amount of rainfall until the last half of August and all of September, when lack of moisture caused considerable injury. The Reddick field in the east north-central section became dry even earlier, and some firing of the lower leaves resulted.

With the exception of the fields at the northern end of the state, the best distribution of rainfall occurred on the Littleton field. The corn on the Mt. Pulaski field in central Illinois and on the Paxton field in the east-central area, which started off nicely, was injured considerably by drouth during the first half of August.

The potential yield of the field at Greenfield was greatly reduced by lack of moisture from mid-June to the second week in August. The hybrids that matured late were even more severely injured than those that matured early. The Sullivan field withstood the drouth; by the middle of September signs of moisture shortage were clearly evident, but yields were not greatly reduced.

The Shobonier field in southern Illinois suffered greatly from early drouth. The plants were so badly stunted that they were not able to recover after the rains of mid-August. A deficiency of potassium and perhaps also of nitrates aggravated the situation on this field.

The Albion field in southeastern Illinois also suffered from early drouth, and leaf firing appeared early. The amount of firing was more than normal, and may have been caused by close planting since the hills were only 3 feet apart each way. In spite of an evident moisture deficiency during a large part of the growing season, the yields from the Albion field were good.

At Modoc in southwestern Illinois there was enough moisture during most of the season to keep the corn growing vigorously. Silking and tasseling occurred earlier at Modoc than at any of the other corn-performance fields.

INSECT PROBLEMS

The season of 1940 presented several insect hazards for corn. The first to attract attention was the attack of the seed-corn maggot, *Hylemyia cilicrura* Rond. This insect, always present in Illinois, damages corn seed when the corn lies ungerminated in the soil or when it germinates very slowly. The cold wet ground at planting time in 1940 delayed the germination of the seed and a great deal of damage resulted. Many farmers found it necessary to replant their fields. It is possible that factors other than the cold wet ground may have been partly responsible for the slow germination and for the consequent losses that were incurred from the seed maggot attack. There was no conclusive evidence that some hybrids are more susceptible than others to damage by the seed-corn maggot, altho hybrids that germinate slowly are probably more susceptible. The performance fields were not seriously affected.

The grape colaspis, *Colaspis brunnea* (F.) was present in great abundance in many Illinois cornfields where corn followed clover, soybeans, and lespedeza. In some places soybean stands were reduced as much as 50 percent, and many fields of corn had to be replanted because of an attack by this insect. There was, however, no particular evidence of the grape colaspis on the performance fields.

There was a threat of chinch bugs, *Blissus leucopterus* (Say), in the early part of the season but they caused very limited damage. They did not affect the performance fields to any considerable extent.

The test fields at Cambridge and Albion were affected to a measurable extent by corn rootworms. The average amount of lodging of hybrids on these two fields was 40.9 and 35.7 percent respectively. (Plants are considered lodged when they lean 30 degrees or more from the perpendicular, this leaning extending to and including the roots.) Examination of other performance fields showed that rootworm damage occurred, but environmental conditions were such that no lodging resulted. Two rootworms, the corn rootworm, *Diabrotica longicornis* (Say), and the southern corn rootworm, *Diabrotica duodecimpunctata* (Fab), were present and contributed to root damage which resulted in the ultimate damage recorded.

DISEASE PREVALENCE

Smut and ear rots were the principal diseases attacking Illinois cornfields in 1940. Only traces of Stewart's disease were seen. Diplodia stalk rot developed only moderately and came too late in the season to decrease yields, but it was no doubt a factor in late-season stalk breaking. There was much lodging from stalk breaking that was not caused by disease, so far as could be ascertained; the

healthy tissues of many of the varieties and hybrids were softer than usual, so that the stalks kinked and fell over easily. Some of the crosses carrying inbred L317 were especially weak in this respect.

Smut. About 4 percent of the 1940 corn crop in Illinois was lost because of smut, as estimated by the authors and by the Illinois State Natural History Survey. This is about twice the average loss. Most of the smut galls in 1940 were located at the ear or at nodes below the ear. Smut above the ear and in the tassel was rare.

Analysis of 1940 data on smut occurrence in single crosses in two fields at Urbana and one at Wyoming showed a negative correlation between smut and yield in each case. This agrees with data obtained by M. T. Jenkins on crosses in Iowa some years ago, and means that in general in years of severe smut occurrence the greater the prevalence of smut in a cross the lower the yield. Of the inbreds that made up these single crosses, 38-11 was the worst in introducing smut-susceptibility, and was followed by WF9, P8, 187-2, and Pr. Among the more resistant inbreds were L317, K4, Kys, 5120, R4, and 28. It is possible that under different growing conditions these rankings might be changed somewhat.

Ear rots. The average kernel damage from rot on all twelve of the corn-performance test fields in 1940 was 2.57 percent; in 1939 it

Smut caused serious reduction in corn yields in 1940

This disease occurred most commonly at nodes below the ear (*left*) and on the ear (*right*). Often the entire ear was converted to smut.

was only 1.68 percent for all fields. This increase was due for the most part to the large amount of ear rot in the two northern fields located at Kings and Round Lake. This area received considerable rain in the late summer, whereas rainfall in most of the remainder of the state was below average during that time.

Diplodia was the principal cause of ear rot in the northern end of the state, where ear rot was most severe. In the remainder of the state Fusarium rot appeared to be the most prevalent.

No advance toward better ear-rot resistance appears to have been made in most of the hybrids that are now in general commercial production. Altho observations have appeared in print stating that the quality of corn has been better during the last few years because more hybrid corn is being grown, the data from the performance tests do not altogether support this view. Either five or six entries of open-pollinated corn were included on each of the twelve performance fields. When the percentage of damaged kernels was averaged separately for all the open-pollinated entries and for all the hybrid entries, the hybrids averaged higher in ear-rot damage on 7 fields, the open-pollinated were higher on 4 fields, and the two were equal on the twelfth field.

Some individual hybrids, of course, have much greater resistance to ear rots than others; the two-, three-, four- and five-year summaries give more reliable data for comparing individual hybrids than do the one-year tables.

MEASURING PERFORMANCE OF ENTRIES

The entries in 1940 were rated, as they were each year since 1935, on the basis of two measures of performance—erect plants at harvest (lodging resistance) and yield of sound corn.

Erect plants. The percentage of erect plants in each entry on each field was estimated at the time of harvest. The *rating* for erect plants of an entry is the ratio of erect plants of that entry to the average number of erect plants on the field, multiplied by 100.

There were three types of lodging on the test fields—that due to rootworm damage, to broken stalks just below the ear, and to broken stalks toward the base of the plant.

Sound corn. To determine shelling percentage, the entire yield from one replicate of each entry was shelled. From this shelled corn one sample was taken to determine the percentage of moisture at harvest, and another to determine the percentage of damaged kernels, by weight. The moisture determinations were made with a Tag-Heppenstall moisture meter. The percentage of damaged corn was determined according to the federal grain standards.

The total acre-yield was calculated as shelled corn carrying 15.5 percent moisture, the upper limit allowable for No. 2 corn. The yield of sound corn was computed by deducting the amount of damaged corn from the total yield.

The rating on sound yield is the ratio, expressed as percentage, of the yield of sound corn for that entry to the average yield of sound corn for all the entries on the field.

General performance. In computing the general-performance rating of an entry, the ratings for erect plants and sound corn were averaged, but the sound-corn rating was given three times the weight of the rating for erect plants. When two or more entries tied in the general-performance rating, the ties were given the same numerical ranking, but they were listed in the order of their descending yield of sound corn. If the two entries had the same yield of sound corn, then they were listed on the basis of total corn.

Chance differences. Too much confidence must not be placed in the exact ranking of a hybrid in the following tables, for chance has played a part in determining the placing of many of them. Unmeasured differences in soil and in prevalence of insects and diseases, and unaccountable variability in stand will cause differences in yield that are not inherent in the hybrids or varieties.

The part played by chance in the 1940 tests has been calculated by the mathematical procedure known as "analysis of variance." At the bottom or side of each table is stated the approximate difference which there must be in the 1940 yields to show a true inherent difference between any two entries. Unless this difference exists there is no assurance that one entry is inherently higher yielding than the other.

Readers are urged to note the difference necessary for significance, as shown for each test field, and to keep that difference constantly in mind in all comparisons of entries on that field.

DISCUSSION OF 1940 TEST

The results of the 1940 corn-performance test brought out some marked differences in hybrids. The year 1940 was not so favorable for corn production as were 1937, 1938, and 1939. In order to perform as consistently as they did, hybrids had to exhibit more resistance to drouth, wind, disease, and insects than in the three years previous. Because of the wind on November 11, the lodging resistance on the Round Lake and Albion fields was important in determining the general-performance rating of the entries on these fields; and in general the entries with the greatest number of standing stalks ranked near the top. Usually the lodging of the hybrids was due to stalk breaking; the open-pollinated varieties went down because of root weaknesses.

Superiority of hybrids. Hybrids were definitely superior to the open-pollinated varieties on all of the fields in the 1940 test. On the Kings, Cambridge, Paxton, and Greenfield test fields the 5 best hybrids exceeded by over 37 bushels an acre the sound yield of the 5 open-pollinated varieties. With the exception of the Littleton field, the 5 poorest hybrids on every field were superior in sound yield to the average of the 5 open-pollinated varieties on the same field. The 5 best hybrids and the 5 poorest hybrids had greater lodging resistance than the average of the 5 open-pollinated varieties on every test field except Round Lake and Albion. On these two fields the 5 poorest hybrids did not stand as well as the open-pollinated varieties. For a complete comparison of the 5 best hybrids and the 5 poorest hybrids with the open-pollinated varieties see Table 3.

With few exceptions the white hybrids that were entered in the test were inferior to the yellow hybrids. Much of the poor performance of the white hybrids was due to the large number of barren stalks. Barrenness also contributed to the poor performance of many of the yellow hybrids but it was not as marked in them as in the white hybrids. Barrenness was the greatest single cause of yield differences on the Paxton field.

Maturity. This year's test was the first in several years in which moisture content at harvest was an indication of maturity. The Round Lake and Kings fields were particularly high in moisture, considering the lateness of harvest.

In order to obtain a better indication of the maturity of the entries on the Kings and Round Lake fields, samples were taken from these fields on October 8 and October 9 respectively. One hill containing at least two plants was harvested from each of four replications. Two

*Average of 6 open-pollinated varieties instead of 5.

complete rows of kernels were removed from every ear harvested to obtain a sample for moisture. The percentage of moisture was obtained by drying 200 grams of the sample in an electric oven for 48 hours.

At Round Lake the moisture content of the samples ranged from 40.2 percent to 25.7 percent (Table 4) on October 9. The average for the 5 adapted open-pollinated varieties was 32.5 percent; and 14 hybrid entries had the same or a lower percentage of moisture. The average for the entire field on October 9 was 33.9 percent, and at harvest (November 15) it was 21.8 percent. The average of the open-pollinated varieties at harvest time was 23.2 percent; and 42 hybrid entries had the same or a lower percentage. The moisture content of the hybrids at harvest time ranged from 28.5 percent to 17.6 percent.

The above data from the Round Lake field indicate that after an early killing frost most hybrids dry out faster than the open-pollinated varieties. In general the hybrids which had the higher percentage of moisture on October 9 had the higher percentage at harvest, and the hybrids with the lower percentage of moisture on October 9 had the least moisture when harvested.

At Kings (Table 6) the situation was much the same as at Round Lake. The moisture content of the grain decreased more rapidly in most of the hybrids than in the open-pollinated varieties. On October 8 the percentage of moisture for all entries on the field ranged from 39.3 percent to 28.0 percent, while at harvest time it ranged from 27.3 percent to 19.6 percent. Eleven hybrids had the same or a lower moisture content than the average of the open-pollinated varieties on October 8; at harvest time 31 hybrids had the same or a lower percentage of moisture than the open-pollinated varieties.

Dropped ears. A count was made of the dropped ears on all of the 1940 test fields, but there were too few such ears to warrant the drawing of any conclusions.

FIVE-, FOUR-, THREE-, AND TWO-YEAR SUMMARIES

A mistake to which all who are interested in hybrid corn are more or less prone is to evaluate a new entry on the results of a single year's test. No two seasons are exactly alike and a corn which does exceptionally well one year may perform quite differently under different seasonal conditions. Manifestly then, the more seasons during which a corn has been tested, the more certain a grower can be of its merit. For this reason summary tables including entries that have been in the tests for five to two years have been prepared.

Not many hybrids have been grown in these tests for as long as five years because most of the hybrids tested five years ago have been

discontinued. A hybrid that ranks well toward the top in the various summary tables and also shows a good performance in the current year's test is most assuredly a good one. The consistency of the general performance of an entry can be readily traced by studying the summary tables for each section of the state.

A good measure of the superiority of an entry is the amount by which it has exceeded the average of the open-pollinated varieties. If the hybrid exceeded the average of the varieties markedly year after year, it is to be preferred to hybrids with widely fluctuating seasonal yields even tho the average yield of the fluctuating hybrids may be somewhat higher.

Differences between yields of hybrids and open-pollinated varieties 1927-1940

The above bars show the amounts by which the yields of the five best hybrids have exceeded (*black*) or have fallen below (*crosshatch*) the five best open-pollinated varieties in three sections of Illinois.

PEDIGREES OF ILLINOIS AND U. S. HYBRIDS

Following is a partial list of Illinois and U. S. hybrids. The performance of those that are starred is shown in this bulletin.

*Less than 5 bushels of seed sampled.

A difference of less than 5.4 bushels between total yields of any two entries in this table is not significant.

Table 7.—NORTHERN ILLINOIS: Kings Summaries

| Rank | Entry | Acre-yield | | Damaged corn in shelled sample | Moisture in grain at harvest | Erect plants | Rating for— | | |
|--|---|-------------|-------------|---|------------------------------------|-----------------|-----------------|----------------|---------------------|
| | | Total | Sound | | | | Erect plants | Sound yield | General perform. |

SOIL ADAPTATION TEST

For the sixth consecutive year studies were made at Sibley and Urbana to determine the adaptability and performance of hybrid corn on soils differing in their productivity. As in the previous years, two tests were conducted at each location, one on a highly productive soil and the other on a soil of medium or low productivity.

Season. Weather conditions in 1940 were not favorable for high yields at either of these locations, altho at Urbana the crop did not suffer as much from adverse weather as it did at Sibley. On the less productive area at Urbana yields were almost as high as in previous more favorable years. Lack of rainfall during most of the growing period was the main cause of low yields.

Soils. The fertile area at Sibley consists of a highly productive Proctor silt loam, and the less fertile area consists of a badly eroded plot of Elliott silt loam. These two soil types and the plots selected within each were good representatives of high and low states of soil productivity. A good crop of sweet clover, which furnished an ample supply of organic matter and of nitrogen, had been plowed down on the Proctor silt loam (high productivity) for the 1940 corn crop. The Elliott silt loam had been limed once and had grown a thin stand of sweet clover; but after a crop of corn had been grown in 1939, the fertility of the field was low. At Urbana the two areas, which are on the Agronomy south farm, differ in productivity as a result of the long-continued use of different cropping systems. In the Southwest rotation a high state of productivity has been maintained by systematically rotating corn, oats, clover hay, and wheat with a red-clover catch crop. The South-Central area has been depleted of fertility by a rotation of corn, corn, corn, and soybeans. Both plots at Urbana have received manure and phosphate. The Southwest rotation has had slightly more limestone than the South-Central. The soil type of the two fields is mainly Muscatine silt loam.

1940 results. In general, the moisture conditions in 1940 were more favorable to corn on soils of medium productivity than to corn on highly productive soils. On the highly fertile soils early growth was stimulated by a combination of a good supply of moisture and a high level of fertility; as a result, the shooting, or ear-making, period of the plant came when the soil was most dry. Where this occurred, ears failed to form and the stalks were barren. Varieties and strains of corn that are normally subject to barrenness were more severely damaged than those not so subject to barrenness. On the high-fertility area at Urbana, wherever the open-pollinated variety had three stalks to a hill, 39 percent of the stalks were barren, and where there were four stalks to a hill, 67 percent were barren. The five best hybrids showed much less barrenness—where there were three stalks to a hill

only 4 percent of the stalks were without ears, and where there were four stalks only 18 percent had no ears.

These data show that in dry seasons on highly fertile soils the yield of thickly planted good hybrids will not be reduced because of stalk barrenness nearly as much as will the yield of thickly planted open-pollinated varieties or of poor hybrids subject to barrenness.

Hybrids on the soil-adaptation fields performed about as they did in the dry season of 1936. Strains such as Illinois 960, Illinois 374, Sibley Farms 588, and Crow 360A, which are generally considered to be widely adapted and particularly suited to poor land, were among the top performers. This was to be expected, for in dry seasons lack

of moisture prevents plant foods from becoming easily available and brings good soil down to the level of poor soil.

Illinois 201 and 247 are newcomers that made a very good showing this year. However, 247 is very susceptible to stalk breaking, and like many of the other widely adapted hybrids it is not so desirable for planting on highly fertile soils, where stalk breaking is often much more severe than on soils of low or medium fertility.

Hybrids stood the drouth much better than the open-pollinated variety. This was particularly true on the high-fertility area at Ur-

bana, where the average of all entries was 36.2 bushels above the yield of Station Yellow Dent and the average yield of the five best hybrids was 44 bushels above the same variety.

Five-year records of two hybrids. Representative of a large group of hybrids that are particularly adapted to highly fertile soils is U. S. 5 (WF9 x 38-11) (R4 x 317), for which a five-year average is given in Table 31, page 219. On the high-fertility area this hybrid has produced 18 bushels (or 20 percent) more than the open-pollinated variety. On the low-fertility area it yielded only 7 bushels, or 15 percent, more. In physical characteristics (which are very important in

| Station Yellow Dent | 69 | ... | 39 | ... |

¹U. S. Hybrid 5 was tested as Illinois 139 in 1936 and in 1937 as a coded commercial hybrid.

determining the adaptability of a hybrid) this hybrid has demonstrated¹ that it has excellent stalk characteristics when grown on fertile soil and very undesirable ear and kernel characteristics when grown on poor soil.

Likewise Illinois 960 (R4 x Hy) (701 x 317) illustrates the performance of the more widely adapted hybrids, which normally do relatively better on medium to poor soils than on good soils. Since this hybrid yields well on good soils as well as on the medium to poor soils it might be concluded that it would, in general, be the more desirable of these two hybrids, but it has very decided stalk weakness that is greatly emphasized on fertile soil¹ even tho it shows very desirable ear and kernel characteristics when grown on poor soil.

SUMMARY

1. The average yield of corn on the twelve fields in the Illinois corn-performance tests in 1940 was 72.1 bushels an acre, which is 28.1 bushels more than the average for the state. During the seven years (1934-1940) over which these tests have been conducted, the average yields on the test fields have exceeded the average yields of the state by 111, 94, 79, 64, 47, 53, and 64 percent respectively.

2. The range in average yield of sound corn on the twelve testing fields was from 25.1 bushels at Shobonier to 92.4 bushels at Kings.

3. The five best hybrids on all twelve fields yielded an average of 27.4 bushels of sound corn an acre more than the five open-pollinated varieties. They also exceeded the open-pollinated varieties in lodging resistance, having 13.4 more erect plants per hundred.

4. On the Kings, Greenfield, Paxton, and Cambridge fields the five best hybrids exceeded the five open-pollinated varieties in yield of sound corn by 50.4, 42.6, 40.8, and 37.9 bushels an acre respectively.

5. On every test field the five best hybrids exceeded the five open-pollinated varieties in yield of sound corn and in percentage of erect plants.

¹See illustrations in Bulletins 450 and 463 of this Station.

6. Except on the Littleton field, the five poorest hybrids in the tests averaged more bushels of sound corn per acre than the open-pollinated varieties.

7. On six of the twelve testing fields all the hybrids exceeded the average of the open-pollinated varieties in performance rating. On the other six fields a total of only 10 hybrids had a lower performance rating than the average of the open-pollinated varieties.

8. Data obtained from the Round Lake and Kings fields indicate that after an early killing frost most hybrids dry out faster than the open-pollinated varieties.

9. Compared with the open-pollinated varieties, the hybrid entries have, on the average, improved thru the years of these tests in yield of sound corn but not in lodging resistance. The average superiority of the hybrids over the open-pollinated varieties was 12.8 bushels an acre for the entries included in the four-year tests, 14.4 bushels for the entries in the three-year tests, and 16.1 bushels in the two-year tests; whereas in erect plants per hundred the average superiority of the hybrids was 14.6, 12.9, and 13.6 for the entries in the four-, three-, and two-year tests.

10. Several insects caused damage to the Illinois corn crop in 1940, but the corn rootworm and the southern corn rootworm were the only ones to cause visible damage on the testing fields and this occurred only on the Cambridge and Albion fields.

11. No advance toward better ear-rot resistance appears to have been made in most of the hybrids that are now in general commercial production. Diplodia ear rot caused much damage on the Kings and Round Lake fields. Fusarium ear rot was prevalent thruout Illinois. Smut caused more damage than usual.

12. In the soil-adaptation tests at Sibley and Urbana hybrids grown on a good soil and under a good soil management responded better to such conditions than did the open-pollinated variety. At Urbana the five best hybrids yielded 23.3 bushels an acre more on the high-fertility area than on the poorer fields. The open-pollinated variety, however, yielded half a bushel less on the better field than on the poorer field.

Hybrids normally ranking high on poor soils ranked high in all the soil-adaptation tests this year, and hybrids normally high on good soils ranked low in all tests.
